THE EFFECT OF SELECTION ON THE NUMBER OF FACETS IN THE EYE OF THE "BARRED-EYE" MUTANT OF DROSOPHILA AMPELOPHILA.

I. Statement of the Problem.

The problem involved in this experiment has been to determine what effect, if any, could be produced by selection in plus and minus directions with regard to the number of facets in the eye of the "barred-eye" mutant of Drosophila ampelophila.

The theroetical problem involved is that of the stability of the germ plasm. If selection on the basis of somatic variation is productive of any effect, there must be a change in the germinal constitution, since the common conception of heredity is based on the organic relation between parent and offspring through the medium of the germ cell.

II. Material and Methods.

The material used in this experiment consisted of a strain of Drosophila known as the "barred-eye" mutant (so-called because the eye is confined to an oblong, bar-like area), which arose in one of Professor Morgan's cultures of wild stock late in 1913. In this strain a considerable variation has been

observed in the number of facets in the eye. The curve of variability for this character in the general population is shown in Figure I.

As the Figure indicates, the number of facets in the eye of the "barred-eye" mutant constitutes a good and feasible basis for selection in that (1) there is a wide range of variation which offers ample room for selection to be made, and (2) the values are definite and may be taken with ease and accuracy.

The method of breeding was to place the individuals selected in 1 ounce salt-mouthed, glass bottles, sterilized before using. The bottles were stopped with cotton to provide for ventilation. The food used consisted of bananas. These were purchased while green, allowed to ripen in a tightly sealed jar, and cooked to the boiling point for ten minutes to avoid contamination by the presence of eggs of the wild species. A small amount of yeast was added to aid fermentation and to prevent the attack of the food by molds.

In making the first selection, food containing eggs and larvae was removed from the culture of the "barred-eye" stock and placed in glass vials. Every twelve hours the individuals which had emerged from the pupal cases were slightly etherized and examined as to the number of facets in the eye under the low power of the microscope. Males and females with high and low numbers of facets were selected out, high being mated with high and low with low. Each pair was placed in one of the small bottles with sufficient food to last until the offspring were all produced.

FIG 1.

When larvae began to appear in one of the bottles, the parents were etherized and the number of facets recorded in each case. They were then preserved in pasteboard boxes bearing proper labels.

As the offspring hatched out they were examined and the highest or lowest individuals, as the case might be, were used to continue the selected stock. At least two pairs from the offspring of each of the original pairs were selected out in this way to continue that particular line. The remainder of the brood were etheriaed and preserved in pasteboard boxes, as were their parents. In this way the parents and offspring of each generation were kept for later reference.

When the first generation of selected stock had been produced it appeared from general observation that as the hatching period progressed the number of facets in the eye increased. Counts were made, therefore, of the number of facets in five broods from the beginning to the end of the hatching period, and it was found that the totals for the individuals produced during the first and second halves of the hatching period were approximately equal.

Late in December (1914), before the third generation of selected stock was completed, the entire stock was killed owing to sudden changes in temperature in the laboratory and also to the food being badly infected by molds. This necessitated starting the experiment all over again. To avoid repetition of the accident the work was practically doubled and two sets of

selected stock were run in different rooms, until the coming of warm weather.

Owing to the fact that an average of twenty-eight days were required for the production of a single generation, only enough time remained after the hatching of the third generation to complete the counts on this and the previous generations for comparison with each other and with the count on the general or unselected population.

When the counting was begun the number of facets in both the right and left eyes was taken on account of there being a slight variation in some cases between the two. For 100 individuals, however, the sums of the facets in right and left eyes respectively, were practically the same, there being a difference of only 0.245 per cent in favor of the left. In subsequent counting the number of facets in the right eye only was recorded.

At the beginning of the experiment eight lines both high and low,sixteen in all, were started from as many pairs of original ancestors. Of these only about 60 per cent were fertile or succeeded in producing any offspring, and by the time the third generation was produced, only four each of these high and low lines remained.

The counting was completed in each generation for three "high" lines called A, B, and C, and for three "low" lines called D, E, and F. Fifty individuals were measured for each generation in each of the lines, with the exception of the third

generation in line B, where only forty-six individuals were available.

In order to determine the range of variability in the general population a count was made of the number of facets in the eyes of 500 individuals. Of these 250 were taken from the cultures of the general population in November 1914, and 250 in April 1915. The mean number of facets for those removed in November was 98.04, and for those removed in April 98.03, with a difference of 0.01. It is evident from this that there is no noticeable tendency for the general population to shift toward a higher or lower number of facets.

The sexual dimorphism in the number of facets does not appear in the data, since the female values were reduced to the respective male values. This was accomplished by dividing the mean male value, 98.035 by the mean female value, 65.06 and multiplying each of the female values by the quotient, 1.51. This reduction made possible the use of mid-parental values in showing the effect of selection in Figures 2, 3, and 4.

III. Data.

In the following Tables the data are given for the counts made in the general population and in lines A, B, C, D, E, and F of the selected population.

IV. Discussion.

Figures 2, 3, and 4 show graphically the effect of selection for three generations as summarized in Table VIII. A study of these figures indicates (1) that the means of the lines in which selection was carried on have been considerably displaced from the mean of the general population, the displacement toward a high number of facets being two to three times as great as that in the opposite direction; (2) that there is in each case, however, a marked regression toward the mean of the general population; (3) that as a result of selection the extremes of variation in the general population have been exceeded in both directions. This is common and of rather surprising magnitude in the case of high selection, but it occurs only once (in the third generation of line D), in the case of the low; (4) that there still exists in the third generation a very considerable overlapping between the populations of the high and low lines. In this generation, however, the means of the high lines, with the exception of line A, are higher than the extreme high variaties in the low lines, and the means of the low lines are appreciably lower in each case than the extreme low variates of the high lines.

Selection, therefore, has proved effective first, in tending to separate two opposite races, and second, in producing new degrees of variation beyond those that exist in the unselected population.

It remains for continued selection to demonstrate to what extent these new degrees of variation produced are heritable. It also remains to test out the pure line hypothesis in determining the extent to which selection is able to isolate lines which breed true and which no amount of subsequent selection can modify. That there are a number of these lines or races differing only slightly from each other in the general population of the "barred-eye" stock, and that many generations of selection will probably be required to isolate these races is indicated by the persistent overlapping already referred to between the populations of the gross divisions of high and low. That these lines are incapable of modification is not evident, however, from the fact that new extremes of variation have been produced within a very few generations of selection.

On the basis of results obtained thus far no definite conclusions can be drawn as to whether selection has or has not effected the stability of the germ plasm. As to the possibility of changing the germinal constitution by selection, different investigators have arrived at opposite conclusions.

Johannsen (1903) working with the common garden bean found that when he selected heavy and light individuals from a general population and sowed them, the resulting crops could be grouped according to their weights in normal curves around the characteristic weights of the parent individuals, rather than around the mode representing the weight of greatest frequency in the general population. Therefore, selection was effective. When,

however, the heavier and lighter individuals were selected from a family raised from a single self-fertilized seed, no further effect of selection could be obtained. Johannsen explains this variation within a pure line as being due to environmental or external rather than internal interferences, which, because they are external, cannot indicate that variations in the offspring of a pure plant are caused by variations in the germ cells from which they were produced.

Jennings (1908), who carried on extensive experiments with Paramecium, arrived at practically the same conclusion as did Johannsen. He found that by progressively selecting in opposite directions with regard to size from a wild culture of Paramecium, it was possible to obtain two lots of very marked difference in size, the difference being hereditary. But when the progeny of a single individual (forming a pure line) were tested, it was found that not the least effect was produced by methodical and long continued selection. Although there were large differences among the individuals in a pure line, these differences were not inherited. Jennings concluded that the effect of his selection consisted "solely in the isolation of races that already existed."

Castle (1914) is one of the investigators who holds an opposite viewpoint. He has experimented with a variety of hooded rat in which selection has been made for increase and decrease in the pigmented area of the coat. The result has been that the average pigmentation in one series steadily increased, while

in the other it steadily decreased. At present the selection has progressed to the extent that the increase and decrease in pigmented area have far transgressed the original limits of variation. Castle's conclusions are that in this case the character acted on by selection has been modified steadily and permanently, and that since the variations of which advantage is taken in selection are inherited, they must have a germinal basis.

Similar results were obtained by DeVries (1903) in an experiment with buttercups in which he succeeded by means of selection in raising the extreme number of petals from eleven to thirty-two.

In general, those who take the positive side of the issue, that the germinal constitution may be modified by selection, base their conclusions upon the results of experimentation with forms which reproduce bisexually. Those who hold the negative view have usually worked with forms reproducing asexually or by means of self-fertilization. Obviously, in the former case there is a greater chance for variations to occur which have a germinal basis and of which advantage may be taken in selection.

V. Summary.

1-As a result of three generations of plus and minus selection the mean number of facets in the "barred-eye" mutant of Drosophila ampelophila was raised from 98.03 to 141.93 and lowered from 98.03 to 81.66. 2- This change was progressive from generation to generation.
